Rule-quench instability in a cellular-automaton market with finite dealer capacity*

Abstract

Can a local rule change destabilize a market that was stable immediately before the change, and how does finite counterparty capacity alter the outcome? We studied a deterministic cellular automaton in which agents held Buy, Hold, or Sell states. Two local rules differed at one neighborhood sum. In each paired rule quench, every site used the baseline rule for 1,000 steps. A preselected fraction then switched rules without resetting the lattice, price, adaptive boundary, trader books, or dealer. No dormant control reached a Sell majority. With an endogenous price boundary and an unlimited dealer, none of 50 runs transitioned at activated fractions 0.10 or 0.15, whereas all runs transitioned at 0.20 or 0.25. The transition remained when the boundary was held fixed. Across lattice sizes $L = 32$–128, the held-boundary midpoint moved from $f_{50} = 0.218$ to 0.166, the transition width narrowed from 0.0275 to 0.0082, and peak ensemble susceptibility increased from 21.2 to 232.7. Dealer capacity changed the financial expression much more strongly than the spatial transition. At $f = 0.20$, median drawdown increased from 0.40% at $h = 0.1$ to 3.92% at $h = 1$ and 25.3% at $h = \infty$. Independent cash and share interventions further separated trader order eligibility from dealer capacity. Time-sliced lattices documented Sell-domain growth across doses and dealer conditions. We used those spatial and finite-size measurements without claiming classical nucleation or an equilibrium universality class.

Preprint.

1 Introduction

Interacting agents can produce large market movements without a comparably large external shock. Herding, imitation, and adaptive strategy models make that possibility explicit [1–4]. Statistical-physics models ask a related question: can a population-level change be organized as a transition controlled by interaction, noise, or composition [5–7]? Most parameter sweeps, however, initialize each parameter value as a separate run. A difference between two such ensembles does not establish that adding a behavior destabilizes a market that was stable immediately before the addition. That causal claim requires a continuous intervention and a matched run in which the intervention remains dormant.

Financial constraints create a separate problem. A trader may want to buy but lack cash, or want to sell but lack shares. An eligible order also needs a counterparty. Stylized price-impact models often replace the counterparty with an implicit reservoir that fills all orders and maps signed flow to a price change [8, 9]. Under that convention, a trader funding shock and a change in market-making capacity can both be called a change in liquidity even though they act at different stages. The distinction matters in a feedback model because execution changes price, price changes the states seen by agents, and those states generate the next orders.

We used a deliberately small model to separate those stages. Agents occupied a square lattice, held Buy, Hold, or Sell states, and updated synchronously from their four nearest neighbors. A three-state Wolfram totalistic rule specified each local update [10, 11]. The baseline and perturbed rules differed at one of nine neighborhood sums, which made the behavioral change exact. Agent states generated unit orders, cash and shares determined order eligibility, an explicit dealer cleared the unmatched residual, and executed imbalance changed the price. Adaptive boundary agents then returned the price signal to the lattice.

The spatial model invited a statistical-physics analysis, but it did not justify a physical mechanism by analogy alone. A growing Sell domain can be measured directly. Classical nucleation would require additional evidence, including a free-energy barrier, thermal activation, surface tension, or a critical droplet. Likewise, a transition curve that sharpens with lattice size may support a finite-size analysis without identifying an equilibrium universality class. We therefore treated domain growth, crossover width, finite-horizon midpoint, and ensemble susceptibility as observables whose claims were limited by the deterministic dynamics and fixed observation time.

In this study, we asked whether activating one local rule destabilized an already stable market and how trader and dealer balance sheets changed its spatial and financial expression. We compared each rule quench with a dormant control, repeated the experiment under endogenous and held boundaries, varied dealer capacity from zero to an unlimited reservoir, and crossed trader cash with trader inventory. Time-sliced market panels documented the spatial paths, while five lattice sizes tested whether the crossover survived changes in system size. The resulting evidence separated the rule-induced spatial instability from price feedback and from the capacity that converted desired orders into executed imbalance.

2 Related Work

2.1 Interaction-driven market dynamics

Agent-based finance explains aggregate fluctuations through interacting, heterogeneous decision makers rather than through a prescribed return process. Fundamentalist–chartist populations, herding models, minority games, and adaptive strategies can generate non-Gaussian fluctuations and volatility clustering [1, 2, 12, 3, 4]. These models establish that simple individual rules can produce complex aggregate behavior. They also establish that interaction structure matters because global coupling, random graphs, and local lattices provide different routes to coordination [13, 14]. Our question was narrower than reproducing the complete set of empirical market statistics [15]. We tested whether a specified local behavior could destabilize a trajectory that was stable immediately before the behavior was activated.

2.2 Lattice models and finite-size transitions

Statistical-mechanics models of markets represent coordination through interacting spins or opinions. Ising-type models combine local herding with global feedback, while three-state models add an inactive state [5–7]. Cellular automata (CA) provide a related but different construction. A lookup table replaces a Hamiltonian and temperature, so the dynamics need not obey detailed balance or possess an equilibrium distribution. Wolfram totalistic rules were useful for our experiment because their local rule space is finite and enumerable [10, 11, 16]. Earlier financial CA studies found abnormal fluctuations and regime changes under local majority or heterogeneous rules [17–19]. We added a paired rule intervention, explicit execution constraints, a boundary control, and a finite-size analysis. Those additions tested causation and robustness without assuming an equilibrium transition.

2.3 Execution, funding, and counterparty capacity

Order-flow models distinguish a desired trade from the transaction that reaches the market. Price-impact relations map signed executed flow to returns [8, 9]. Market microstructure and funding-liquidity studies further explain how counterparty and balance-sheet constraints can amplify or stop feedback [20, 21]. A trader cash constraint and a dealer inventory constraint are therefore not interchangeable. The first makes a buy ineligible before matching; the second rejects an eligible order that remains unmatched. Our dealer was intentionally simpler than a limit-order book. Opposing agent orders cleared first, and only their residual used dealer cash or inventory. This accounting placed finite dealers and the unlimited reservoir in one model family. Crossing dealer capacity with trader cash and share interventions then identified which balance sheet constrained each link. The interventions were model experiments, not calibrated policy experiments.

3 Methods

3.1 Three-state cellular automaton

Agents occupied an $L \times L$ square lattice and carried one of three states: Buy ($s = 0$), Hold ($s = 1$), or Sell ($s = 2$). We refer to the synchronous local update as a cellular automaton (CA). Only the $(L-2)^2$ strictly interior cells followed the CA rule. For interior cell i, we calculated the sum of its four cardinal-neighbor states as:

$$c_i(t) = \sum_{j \in \partial i} s_j(t) \in \{0, 1, \ldots, 8\}. \tag{1}$$

A totalistic rule maps each possible sum to one of the three states. Writing the nine outputs as ternary digits $a_j = \mathcal{R}(j)$ gave the Wolfram rule index:

$$R = \sum_{j=0}^{8} a_j 3^j. \tag{2}$$

The numerical state labels therefore entered the dynamics through both the neighborhood sum and the rule table.

We used Rule 19280, $(222110002)_3$, as the baseline and Rule 19286, $(222110022)_3$, as the perturbed rule. The tables differed only at $c = 1$. A neighborhood with three Buy cells and one Hold cell therefore returned Buy under Rule 19280 and Sell under Rule 19286. We used the term *contrarian* only for that specific local response. For each run, we selected a fraction f of interior sites uniformly without replacement and kept that target set fixed. All target sites initially used Rule 19280 and changed to Rule 19286 only at the intervention step. The initial interior contained exactly 5% Buy and 5% Sell sites placed without replacement, with Hold elsewhere. Randomness entered through that initial placement, the target set, the active boundary sample, boundary band widths, and finite-dealer rationing. Conditional on the seed, the complete dynamics were deterministic.

3.2 Orders, trader books, and dealer clearing

Every interior cell and every active boundary cell represented a trader. A Buy state submitted one unit buy order, a Sell state submitted one unit sell order, and a Hold state submitted no order. Trader

i carried cash w_i, integer inventory q_i, and average acquisition cost $\bar{c}_i$. A buy was eligible when $w_i \geq P_{t-1}$, and a sell was eligible when $q_i \geq 1$. We disabled the optional cost-basis restriction in the principal experiments, so average cost did not prevent a sale. We recorded an order that failed these tests as *agent-suppressed*. Suppression changed the financial execution, not the trader's CA state.

We let B_t and S_t denote the eligible buy and sell counts at the standing quote P_{t-1}. Opposing flow of size $\min(B_t, S_t)$ cleared without using dealer capacity. The residual went to an explicit dealer. Dealer capacity was an intensive quantity $h \geq 0$ in net units per trader. For N_{tr} traders, we set $H = \mathrm{round}(hN_{\mathrm{tr}})$. A finite dealer began with cash $W_0 = P_0 H$ and inventory $Q_0 = H$, could not borrow, and satisfied $0 \leq Q_t \leq 2H$. When buys exceeded sells, the executed counts were:

$$n_t^S = S_t, \qquad n_t^B = S_t + \min(B_t - S_t, Q_{t-1}). \tag{3}$$

When sells exceeded buys, the corresponding counts were:

$$n_t^B = B_t, \qquad n_t^S = B_t + \min\left(S_t - B_t, 2H - Q_{t-1}, \left\lfloor \frac{W_{t-1}}{P_{t-1}} \right\rfloor\right). \tag{4}$$

We recorded eligible units beyond these bounds as *dealer-rejected*.

When the dealer rejected part of the excess side, a counter-based score keyed by seed, step, trader identity, and side supplied a new reproducible priority ordering. The time key prevented the same trader from retaining priority at every step. Filled orders updated trader books at P_{t-1}. The dealer received the opposite cash and share transfers, which gave its ledger update:

$$Q_t = Q_{t-1} + n_t^S - n_t^B, \; W_t = W_{t-1} + P_{t-1}(n_t^B - n_t^S). \tag{5}$$

Total cash and shares over traders plus dealer were conserved when no balance-sheet intervention occurred. The $h = \infty$ limit started from a zero dealer ledger, permitted borrowing and shorting, and filled every eligible order. It was the unlimited limit of the same clearing rule, not a separate execution model.

3.3 Price feedback and the held-boundary control

Only executed orders moved the price. We calculated normalized executed imbalance as:

$$\phi_t = \frac{n_t^B - n_t^S}{N_{\mathrm{tr}}}. \tag{6}$$

The imbalance updated the standing quote according to:

$$P_t = P_{t-1} \exp(\lambda \phi_t). \tag{7}$$

The principal experiments used $P_0 = 100$ and $\lambda = 0.02$. Active boundary traders classified the new quote against an exponential moving center and an exponential moving absolute deviation. We updated those quantities as:

$$\mu_t = \mu_{t-1} + \alpha(P_t - \mu_{t-1}), \; \sigma_t = \sigma_{t-1} + \alpha(|P_t - \mu_t| - \sigma_{t-1}), \tag{8}$$

where $\alpha = 1/60$. Boundary trader j had a fixed half-width $k_j \sim U[k(1-\delta), k(1+\delta)]$, with $k = 1$ and $\delta = 0.5$. It took Buy below $\mu_t - k_j \sigma_t$, Sell above $\mu_t + k_j \sigma_t$, and Hold inside the band. One quarter of perimeter cells were active, and the rest stayed at Hold.

The simulation wrote the new boundary state before it updated the interior. The complete feedback sequence was:

$$\text{CA state} \to \text{orders} \to \text{dealer fills} \to P_t \to \text{boundary state} \to \text{CA state}.$$

The implementation applied rule activation, any balance-sheet intervention, eligibility tests, clearing, settlement, price formation, boundary classification, and the synchronous CA update in that order (Algorithms S1 and S2). The matched *held-boundary* control retained the same initial lattice, target rule field, active edge coordinates, band draws, books, dealer, orders, and price calculation, but replaced every active boundary state with Hold before the interior update. Financial state continued to evolve in this arm, but it could not return to the lattice. The held boundary therefore isolated the autonomous spatial response.

3.4 Paired rule-quench experiments

Every principal experiment began with Rule 19280 at every interior site. The system evolved for $T_{\mathrm{pre}} = 1{,}000$ steps before any rule changed. At the top of step $T_{\mathrm{pre}} + 1$, the treated arm activated Rule 19286 at the preselected fraction f; the dormant arm left the same target sites on Rule 19280. Neither arm reset the lattice, quote, adaptive bands, trader books, or dealer. The two paths were identical through $X_{T_{\mathrm{pre}}}$. The next quote was also identical because it came from that common state, and the first possible difference occurred in the following interior update. We verified these equalities bit for bit for every pair.

The dealer-capacity screen used $L = 64$, 3,000 post-activation steps, and 50 seeds. The fraction grid was 0.10, 0.15, 0.175, 0.185, 0.190, 0.195, 0.200, 0.205, 0.210, 0.225, and 0.250. Dealer capacity took values 0, 0.1, 0.5, 1, 2, 5, 10, and ∞ under endogenous and held boundaries. Traders began with cash 1,000 and 10 shares. The finite-size experiment used $L \in \{32, 48, 64, 96, 128\}$ and three arms: held boundary with $h = \infty$, endogenous boundary with $h = \infty$, and endogenous boundary with $h = 1$. It sampled 12 fractions from 0.140 to 0.250 over 50 seeds. Because h was defined per trader, absolute dealer capacity scaled with lattice size.

The balance-sheet experiment changed trader funding and sell inventory at the same top-of-step event as rule activation. We multiplied current cash and current shares independently by $g_w, g_q \in \{0.1, 1, 10\}$ and rounded shares to integers. The full 3×3 design was crossed with $f \in \{0.170, 0.175, 0.180, 0.185\}$, $h \in \{0.1, 1, \infty\}$, both boundary conditions, and 50 seeds. All nine interventions within a $(f, h, \text{boundary}, \text{seed})$ cell shared an identical pre-intervention path. Under the held boundary, their full lattice paths also had to remain identical after the intervention. That equality supplied an exact null test for a direct effect of financial variables on the interior rule.

3.5 Spatial panels, outcomes, and reproducibility

We chose the time-sliced market panels from ensemble summaries before inspecting their lattice images. The dose atlas included a nontransitioning $f = 0.15$ run, both outcome groups at $f = 0.175$, and transitioning runs at $f = 0.185$ and 0.20 under $h = \infty$. Within each transitioning group, we chose the onset nearest the subgroup median. Within each nontransitioning group, we chose the final Sell fraction nearest the subgroup median. The dealer atlas required a seed that transitioned at $h = 0.1$, 1, and ∞ for $f = 0.20$. Among those seeds, we minimized the summed distance from the three capacity-specific median onsets. Both atlases displayed the lattice at fixed offsets 0, 500, 1,500, and 3,000, so rows shared one clock.

The order parameter $m(t)$ was the strictly interior Sell fraction. We called a run transitioned when $m(t) \geq 0.5$ at least once after activation and defined onset as the first crossing. We reported transition probability, onset conditional on crossing, the final 500-step mean of $m(t)$, maximum post-activation drawdown, agent-suppression fractions, and the fraction of eligible orders rejected by the dealer. At fixed (L, f, h), we measured between-seed fluctuations of the final-window mean $\bar{m}$ with the ensemble susceptibility:

$$\chi_L = (L-2)^2 \left[\langle \bar{m}^2 \rangle - \langle \bar{m} \rangle^2 \right]. \tag{9}$$

We linearly interpolated the sampled transition curve to estimate the finite-horizon midpoint $f_{50}(L)$ and the width $f_{75}(L) - f_{25}(L)$. These quantities described the sampled crossover and were not treated as equilibrium critical parameters.

Binomial proportions used 95% Wilson intervals, and continuous summaries used interquartile ranges unless noted otherwise. A seeded Xoshiro generator produced the setup draws. Each production cell wrote an atomic checkpoint, and aggregation reconstructed a fixed row order, so thread scheduling and restart order did not alter the results. Unit tests covered parameter validation, finite-dealer limits, time-varying reproducible priorities, conservation, delayed rule activation, the held-boundary control, and exact reproduction of the earlier fill-all path at $h = \infty$. Step-by-step tests also compared the optimized CA kernel with the general totalistic solver for homogeneous and heterogeneous rule fields.

4 Results

4.1 Rule activation destabilized a stable market

The paired quench tested whether the rule change, rather than a different initial condition, caused the Sell-dominated state. Treated and dormant paths were bit-identical during the 1,000-step baseline and through the first quote after activation. None of the 50 dormant controls reached a Sell majority in the next 3,000 steps. Treated runs at $f = 0.10$ and 0.15 also remained in the mixed state, while activation at $f = 0.20$ and 0.25 shifted both the median price and median Sell fraction away from their paired controls (Fig. 1A,B). In the representative $f = 0.20$ pair selected by the median-effect rule, the two arms shared the same lattice at activation. The dormant arm remained mixed, whereas the treated arm formed expanding Sell regions and ended in a Sell-dominated state (Fig. 1C). Because the intervention changed only the active rule labels, the post-activation divergence identified a causal effect of Rule 19286 within this model.

The coarse paired experiment separated two regimes. None of the treated runs at $f = 0.10$ or 0.15 crossed the Sell-majority threshold, whereas all 50 runs crossed at $f = 0.20$ and 0.25. Median time from activation to crossing was 1,044.5 steps at $f = 0.20$ and 311.5 steps at $f = 0.25$. The experiment therefore established that activating the local response could move an already evolving baseline market into a Sell-dominated state. It did not locate the lower edge of the crossover, which required the finer screen below.

4.2 Dealer capacity controlled price movement more than crossing

The fine screen first located the crossover under an unlimited dealer. At $f = 0.175$, 14 of 50 runs crossed the Sell-majority threshold. The count increased to 43 at $f = 0.185$, 46 at $f = 0.190$, and 50 at every sampled fraction from $f = 0.195$ upward (Fig. 2A).

The held-boundary experiment asked whether price feedback was required for the spatial transition. Its lattice path was exactly invariant to dealer capacity for each (f, seed) pair, although executions, prices, and dealer ledgers differed. Transition probability under the held boundary rose from 0.34 at $f = 0.175$ to 0.70 at 0.185, 0.90 at 0.190, 0.98 at 0.195, and 1.00 at 0.20 (Fig. 2A). The transition therefore occurred when financial state was prevented from entering the lattice.

Restoring the endogenous boundary changed crossing probability only within the same narrow window. At $f = 0.175$, probability ranged from 0.28 under the unlimited dealer to 0.66 at $h = 0.1$, compared with 0.34 under the held boundary. At $f = 0.185$, the endogenous range was 0.84 to 0.98, compared with 0.70 under the held boundary (Fig. 2A,B). The ordering was not monotone in h. All capacities produced no transitions at $f \leq 0.15$ and nearly universal transitions by $f \geq 0.20$. Price feedback therefore changed marginal outcomes but did not create the transition window.

Dealer capacity had a larger and ordered effect on price. At $f = 0.20$, median maximum drawdown increased from 0 at $h = 0$ to 0.40%, 1.98%, 3.92%, 7.69%, and 18.1% at $h = 0.1, 0.5, 1, 2$, and 5, then reached 25.3% at $h = \infty$ (Fig. 2C). Median dealer rejection moved in the opposite direction, from 0.449 at $h = 0$ to 0.118 at $h = 5$ and zero at $h = \infty$ (Fig. 2D). Capacity $h = 10$ reproduced the unlimited path in this campaign. Capacity $h = 0$ permitted only matched flow, fixed the price, and reproduced the held-boundary lattice. These limiting cases showed that dealer depth set how much net flow reached the price, while the rule mixture made a Sell-domain transition possible.

4.3 Time-sliced markets revealed several paths through the crossover

The dose atlas tested whether the aggregate crossing curve concealed one special-looking exemplar. At $f = 0.15$, the selected run retained a fine mixed pattern for the full 3,000 steps. The two $f = 0.175$ runs had different outcomes despite sharing the same rule fraction: one developed Sell-rich regions but stayed below one-half, while the other formed a large connected Sell domain and crossed after 2,186 steps. The selected $f = 0.185$ run crossed after 1,779 steps through several connected regions, whereas the $f = 0.20$ run crossed after 1,030 steps and ended with one dominant Sell domain (Fig. 3A). Their price and Sell-fraction paths placed the fixed snapshots on the aggregate trajectories (Fig. 3B,C). Thus the transition probability summarized a distribution of spatial paths rather than a synchronous change of every cell.

The spatial evidence supported domain growth but not classical nucleation. Sell-rich regions enlarged and merged in each selected crossing, but their number, shape, and crossing time differed across disorder realizations. The noncrossing $f = 0.175$ run also formed a visible Sell-rich region, showing that a domain was not sufficient to guarantee a finite-horizon majority. The model had no free-energy functional, thermal activation process, surface tension, or derived critical droplet. We therefore used the market panels to establish spatial organization and reserved the size dependence for a separate test.

4.4 Matched market panels separated spatial and financial responses

The matched-seed atlas asked how the same rule landscape developed under finite and unlimited dealers. Seed 25 was selected jointly from runs that crossed at $h = 0.1$, 1, and ∞. All three endogenous runs formed expanding Sell domains and crossed within 88 steps of one another, at 1,045, 1,110, and 1,022 steps, respectively. The held-boundary run crossed at 1,191 steps (Fig. 4A). Dealer capacity changed the detailed domain geometry and timing, but every run reached a similar Sell-dominated final state.

The matched financial paths were much farther apart than the crossing times. The $h = 0.1$ price changed by less than one percent, the $h = 1$ price fell by about four percent, and the unlimited-dealer price fell by about one quarter over the displayed horizon (Fig. 4B). The four Sell fractions nevertheless passed one-half in the same broad time interval and ended between about 0.82 and 0.88 (Fig. 4C). The held boundary still calculated executions and price, so its price was not fixed; only the return path from price to lattice was removed. These matched panels made the aggregate result concrete: a constrained dealer could nearly remove the drawdown without removing Sell-domain growth at $f = 0.20$.

4.5 The crossover sharpened and shifted with lattice size

The size experiment tested whether the $L = 64$ crossover was a single-size artifact. No dormant control transitioned at any sampled size. Under the held boundary, the treated midpoint moved from $f_{50} = 0.2181$ at $L = 32$ through 0.1926, 0.1777, and 0.1681 to 0.1665 at $L = 128$ (Fig. 5A,C). The width $f_{75} - f_{25}$ decreased from 0.0275 to 0.0082. Peak ensemble susceptibility increased from 21.2 to 232.7 and moved from $f = 0.225$ to $f = 0.170$ (Fig. 5B,D). Increasing system size therefore sharpened rather than erased the finite-time crossover over the range tested.

The endogenous arms followed the same size trend. At $L = 32$, midpoint estimates were 0.2132 for $h = \infty$ and 0.2100 for $h = 1$, compared with 0.2181 for the held control. At $L = 128$, the three estimates were 0.1655, 0.1650, and 0.1665, and their widths lay between 0.0063 and 0.0082 (Fig. 5C). Susceptibility peaks increased in every arm. The convergence indicated that boundary feedback and dealer capacity changed finite-size corrections more than the large-L midpoint over the sampled range. Five sizes and a fixed 3,000-step horizon were not sufficient to fit a critical exponent or establish a thermodynamic transition.

4.6 Trader and dealer balance sheets constrained different links

The crossed balance-sheet experiment first tested whether financial variables could affect the lattice without price feedback. Within every held-boundary (h, f, seed) cell, all nine cash and share multipliers produced bit-identical lattice paths. Transition probability at $f = 0.18$ was therefore 0.64 in every held-boundary financial cell. Under the endogenous boundary, the same probability ranged from 0.50 to 0.94 across the three-by-three cash–share grid and three dealer capacities (Fig. 6A–C). Financial interventions could change the lattice only through executed flow, price, and the boundary.

Trader inventory produced a large drawdown only when the dealer could absorb the resulting flow. At baseline cash and $h = \infty$, share multipliers 0.1, 1, and 10 produced median maximum drawdowns of 2.87%, 20.1%, and 83.5% (Fig. 6D). The corresponding values were 0.040%, 3.92%, and 3.92% at $h = 1$, and 0.025%, 0.399%, and 0.399% at $h = 0.1$ (Fig. 6E,F). Once dealer inventory bound, additional eligible sells became rejections rather than additional executed imbalance. Trader shares set potential sell flow, while dealer inventory capped the unmatched part that reached the price.

Crossing probability did not increase monotonically with drawdown. At $h = 1$ and baseline cash, the share-0.1 arm transitioned in 0.94 of seeds with only 0.040% median drawdown, while the share-10

arm transitioned in 0.60 with 3.92% drawdown. At baseline shares and $h = 1$, multiplying cash by 10 reduced median drawdown from 3.92% to 0.089% but increased transition probability from 0.78 to 0.94. Trader cash supplied matching buy flow and also changed the boundary signal. The intervention therefore separated three outcomes that a single crash label would conflate: Sell-state dominance, price drawdown, and dealer rejection.

5 Discussion

The rule quench changed the claim that could be made about the instability. A fixed-composition sweep can establish that two parameter settings have different outcomes, but it cannot establish that adding a behavior destabilizes a market that was stable immediately beforehand. Here, treated and dormant arms shared the realized lattice, books, dealer, price, adaptive bands, and latent target sites until activation. Their later divergence was therefore a causal effect of the rule switch within the model. The experiment did not establish that a comparable fraction of real traders would produce the same outcome because neither the rule pair nor f was calibrated to market data.

The held-boundary control located the main instability in the heterogeneous cellular automaton. Sell-majority crossings remained when price could not return to the lattice. Restoring the feedback loop moved probability and onset inside the crossover window, but the response to dealer capacity was not monotone. The adaptive boundary changed state when price crossed a moving band, so additional executed flow could alter both the sign and timing of its later influence. A single scalar liquidity parameter would hide that state-dependent feedback.

Dealer capacity had a simpler effect on price. A finite dealer left desired states unchanged and cleared all opposing agent flow. It truncated only the unmatched eligible residual. The resulting drawdown ladder followed directly from the amount of residual that could execute. At $h = 0$, executed buys and sells balanced and the quote stayed fixed. At $h = \infty$, the quote absorbed the complete eligible imbalance. The time-sliced dealer comparison made the separation visible: similar Sell-domain growth occurred with almost no price movement at $h = 0.1$ and a large drawdown at $h = \infty$. Dealer capacity was therefore a useful experimental control, although the dealer was not a realistic model of market depth.

The spatial evidence supported a nonequilibrium domain-growth description. Across doses and seeds, Sell-rich regions formed, enlarged, and merged rather than appearing through one synchronous relabeling. Both outcomes at $f = 0.175$ also showed why one attractive exemplar would have been insufficient: a visible domain could remain below the finite-horizon majority threshold. The analysis did not supply the ingredients of classical nucleation. No free-energy barrier, thermal activation rate, surface tension, or critical droplet was derived. Domain growth was therefore an observed spatial pattern, not evidence for a nucleation mechanism.

The finite-size measurements strengthened the spatial claim without turning it into an equilibrium claim. The held-boundary transition narrowed, its susceptibility peak increased, and its midpoint approached the same range as the two endogenous arms. The $L = 64$ crossover was therefore not erased at larger sampled sizes, and dealer and boundary effects appeared mainly in the finite-size corrections. Establishing an asymptotic transition would require larger lattices, longer size-dependent horizons, denser sampling near the peak, and a scaling model specified before fitting. Those calculations would also need to distinguish a diverging correlation length from long transient coarsening near an absorbing state.

The balance-sheet experiment separated trader eligibility from counterparty capacity. Trader shares determined how much sell flow could be offered, trader cash supplied eligible buy flow, and dealer cash and inventory limited the unmatched residual. Large trader inventories therefore caused an extreme drawdown against an unlimited dealer but mainly caused rejection against a constrained dealer. The exact held-boundary null further established that financial interventions affected lattice outcomes only through the price-to-boundary link. Price drawdown, Sell-state dominance, and dealer exhaustion should therefore remain separate reported outcomes.

Several limitations bounded the study. The cellular automaton was deterministic conditional on its seed, updated synchronously, and used a regular lattice and one selected rule pair. Orders had unit size and a common standing quote. The model had no order book, bid–ask spread, cancellation, strategic dealer, risk penalty, or endogenous capacity replenishment beyond reversing flow. Boundary

traders used one adaptive rule, and uniform balance-sheet multipliers were causal model interventions rather than policy models. Finally, the price-impact coefficient, time step, and lattice geometry were dimensionless and uncalibrated. The findings therefore identified mechanisms in a minimal dynamical system and did not forecast market crashes.

6 Conclusion

Activating one local response destabilized market paths that had remained stable under the baseline rule. The paired design established that claim without comparing separately initialized regimes. Crossings also occurred under the held boundary, and the crossover sharpened as lattice size increased. Time-sliced markets showed Sell-rich regions growing and merging across doses, seeds, and dealer conditions. Together, the intervention, spatial panels, and finite-size measurements identified a robust spatial instability while leaving classical nucleation and an equilibrium critical point unclaimed.

The explicit dealer separated that spatial instability from its financial expression. Dealer capacity strongly ordered drawdown and rejection but changed transition probability mainly inside the narrow crossover. Trader shares set potential sell flow, trader cash supplied matching buy flow, and dealer resources capped the unmatched flow that reached the quote. Sell-state dominance, price decline, and dealer exhaustion could therefore move separately. The unlimited dealer remains a useful mathematical limit, but it is not an innocuous assumption about execution.

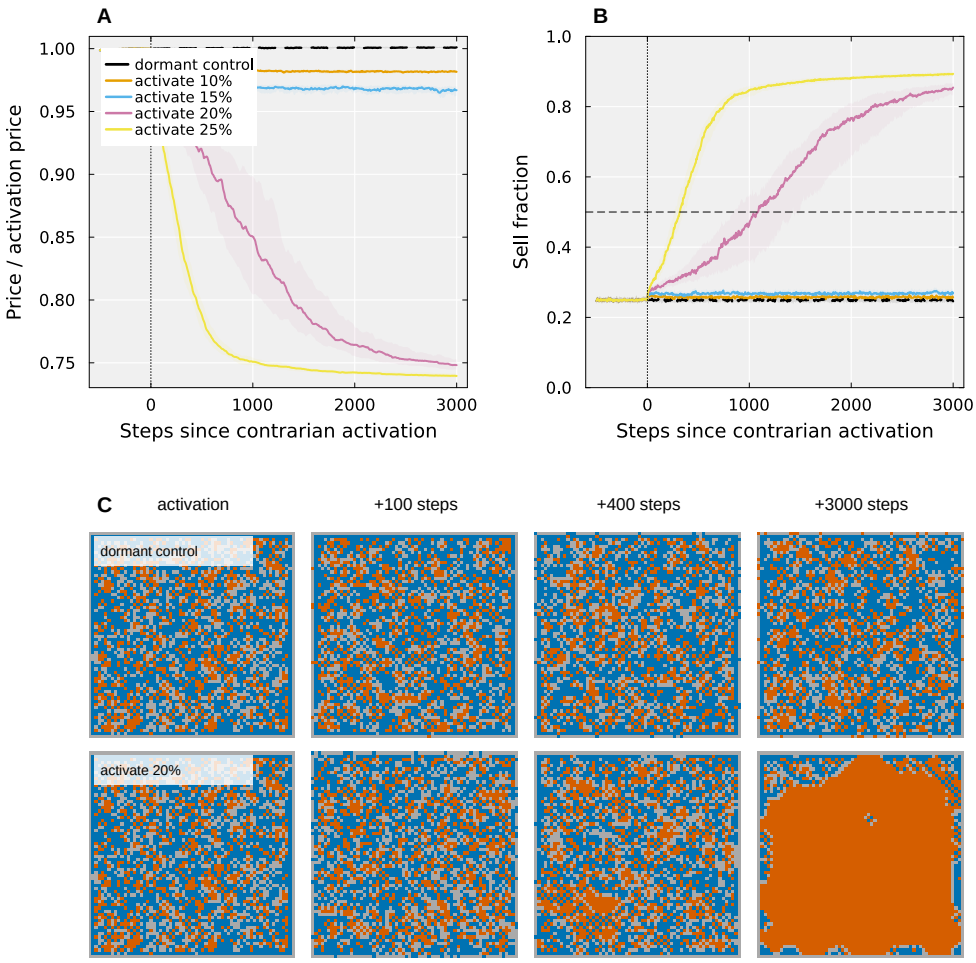

Figure 1: A paired rule quench separated initially identical markets. Fifty seeds were run on a 64×64 lattice for 1,000 baseline steps and 3,000 post-activation steps. The dormant arm retained the same target sites but did not switch their rules. **(A)** Median price divided by its value at activation; bands mark the interquartile range. **(B)** Median interior Sell fraction; the horizontal line marks the majority threshold. **(C)** Time-sliced lattices for seed 12, the $f = 0.20$ pair nearest the median treated-control peak-Sell difference. Blue, gray, and orange cells denote Buy, Hold, and Sell. The two rows show the dormant and treated arms from their common activation state through 3,000 steps. All paired paths coincide before the vertical activation line.

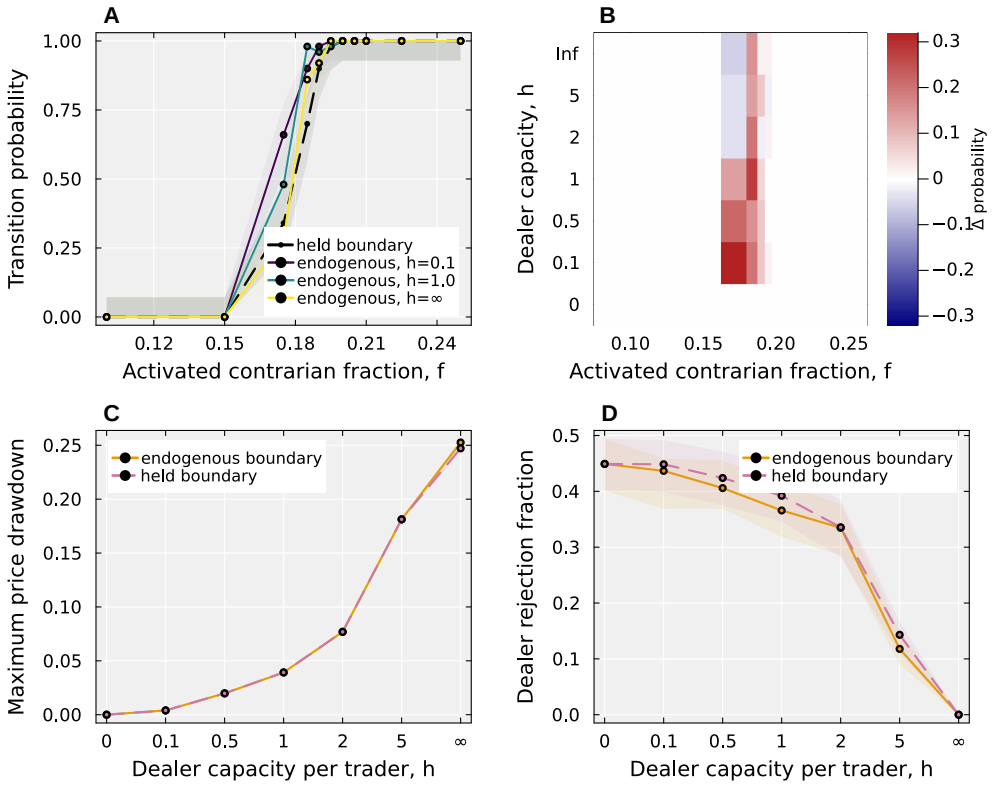

Figure 2: Rule activation across explicit dealer capacities. **(A)** Transition probability under the held boundary and three endogenous dealer conditions; bands are 95% Wilson intervals over 50 seeds. **(B)** Difference between endogenous and held-boundary transition probabilities across the complete capacity ladder. **(C)** Median maximum drawdown at $f = 0.20$; bands mark the interquartile range. **(D)** Median fraction of agent-eligible orders rejected by the dealer at $f = 0.20$. Capacity $h = 10$ is omitted because it coincided exactly with $h = \infty$ in this campaign.

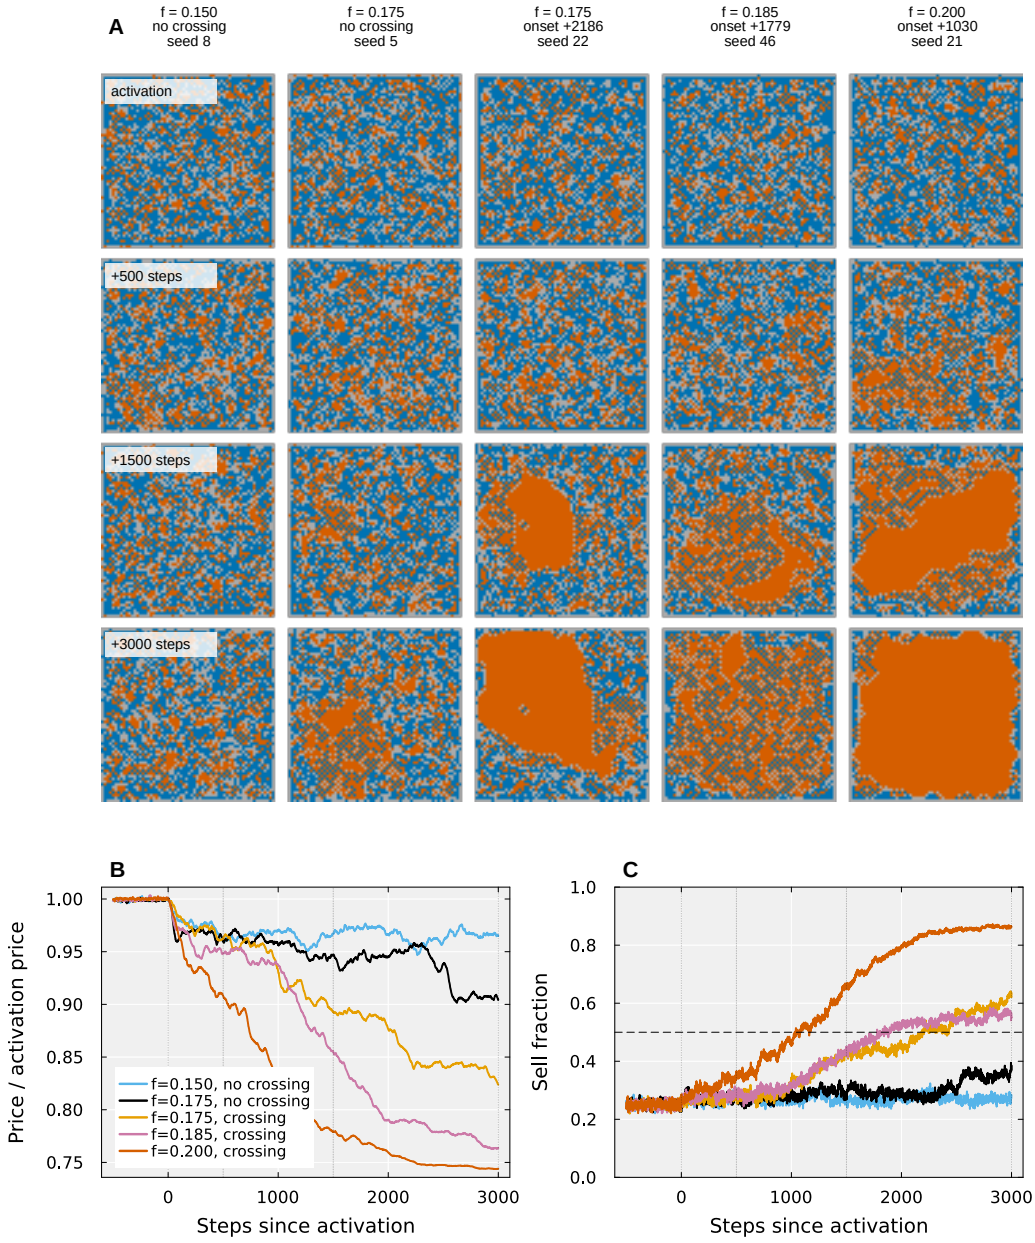

Figure 3: Prespecified time-sliced markets across the rule-dose crossover under an endogenous boundary and unlimited dealer. Blue, gray, and orange cells denote Buy, Hold, and Sell. **(A)** Lattices for five runs (columns) at activation and after 500, 1,500, and 3,000 steps (rows). From left to right, the runs include a noncrossing $f = 0.15$ case, both outcome groups at $f = 0.175$, and crossing cases at $f = 0.185$ and 0.20. Crossing cases were nearest their subgroup median onset; noncrossing cases were nearest their subgroup median final Sell fraction. Seeds were 8, 5, 22, 46, and 21 from left to right. **(B)** Price divided by its activation value. **(C)** Interior Sell fraction; the horizontal line marks the majority threshold. Vertical guides mark the four snapshots.

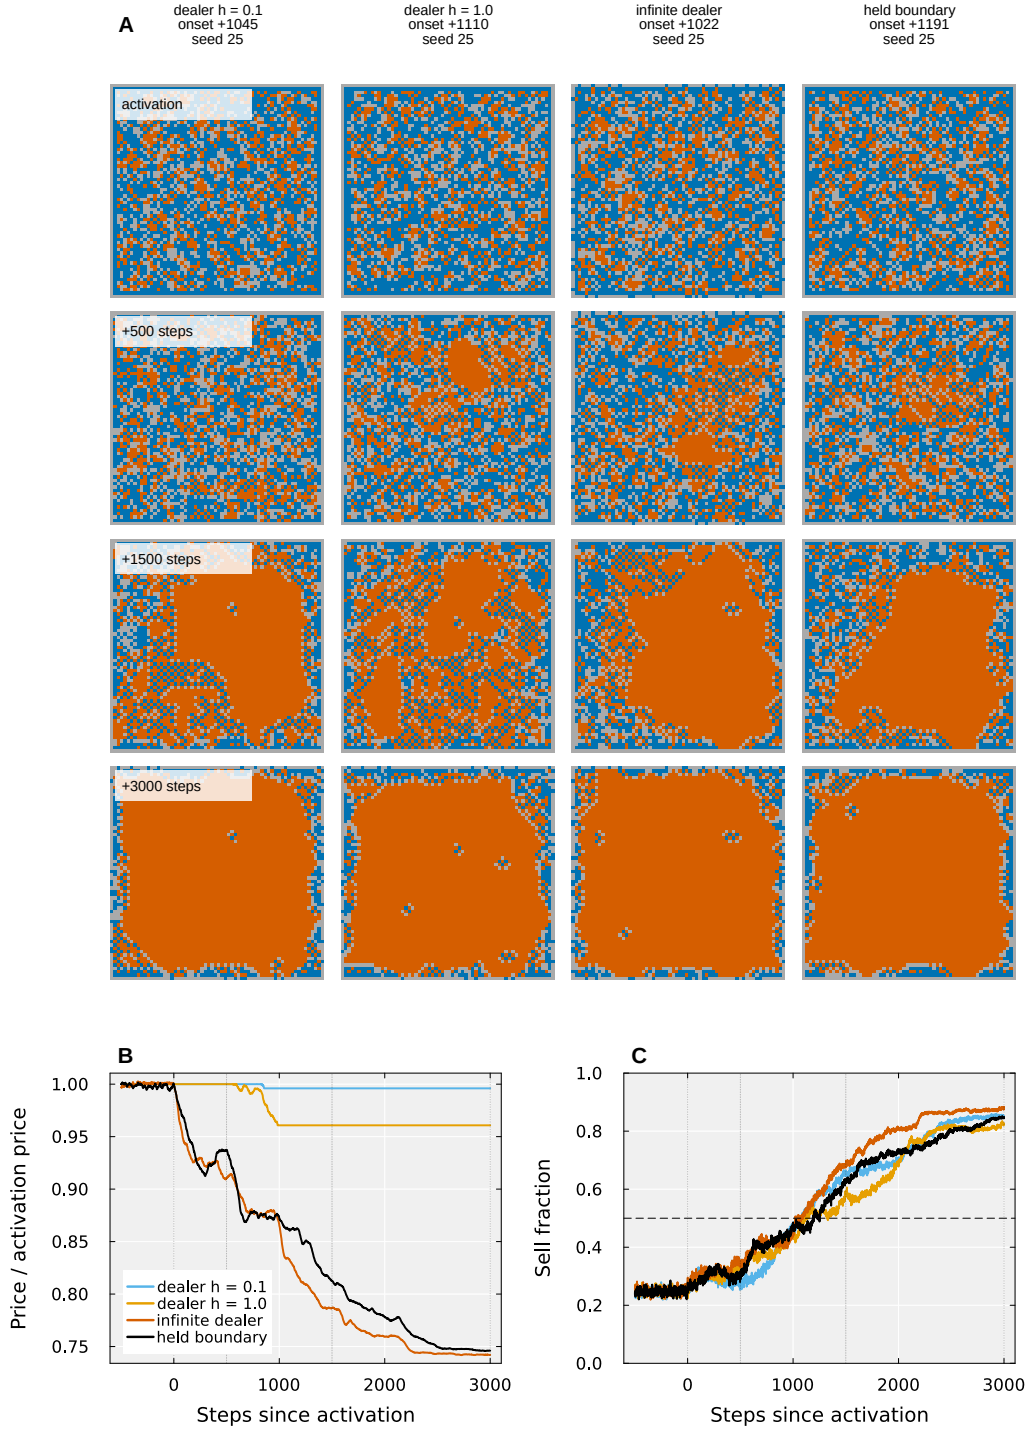

Figure 4: Time-sliced markets for one matched seed at $f = 0.20$. **(A)** Lattices for four conditions (columns) at activation and after 500, 1,500, and 3,000 steps (rows). From left to right, the columns contain endogenous dealers $h = 0.1$, $h = 1$, and $h = \infty$, followed by the held-boundary control with $h = \infty$. Seed 25 minimized the summed distance from the three endogenous capacity-specific median onsets among seeds that crossed in all three conditions. Rows use common elapsed times. **(B)** Price divided by its activation value. **(C)** Interior Sell fraction. The held boundary prevented price from changing the lattice; it did not prevent the price from being calculated.

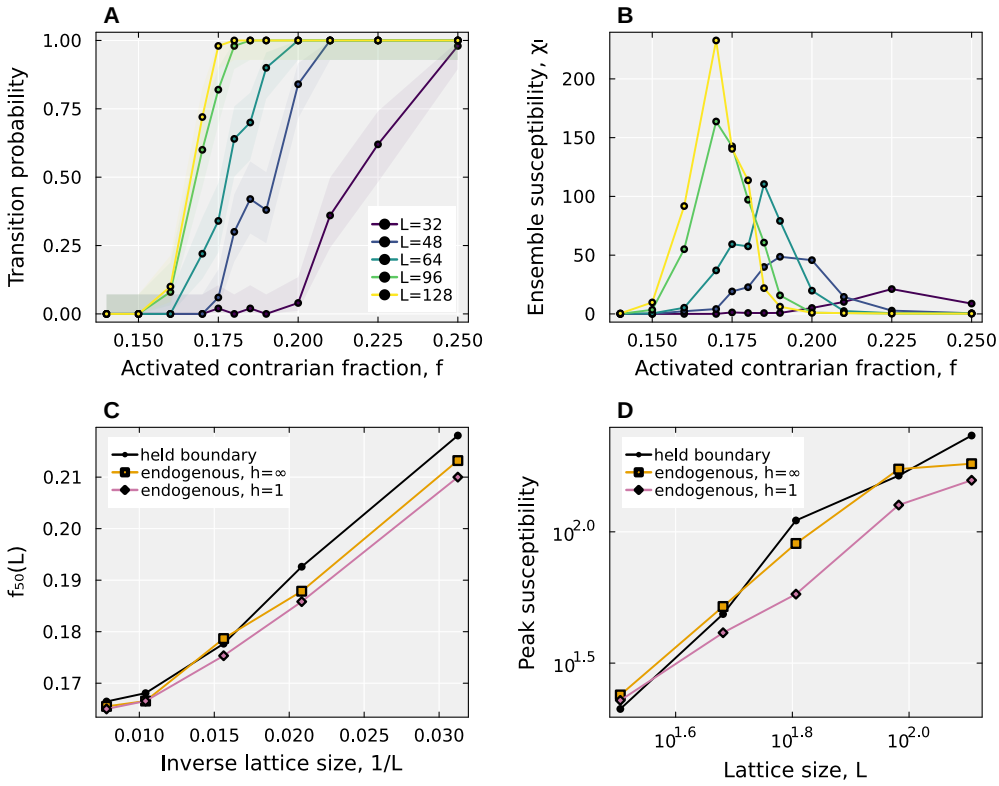

Figure 5: Finite-size response of the paired rule quench over 50 seeds. **(A)** Held-boundary transition probability; bands are 95% Wilson intervals. **(B)** Held-boundary ensemble susceptibility of the final 500-step Sell fraction. **(C)** Interpolated finite-horizon midpoint $f_{50}(L)$ for the held control and two endogenous dealer conditions. **(D)** Peak susceptibility versus lattice size on logarithmic axes. Lines connect sampled values; no asymptotic scaling law was fitted.

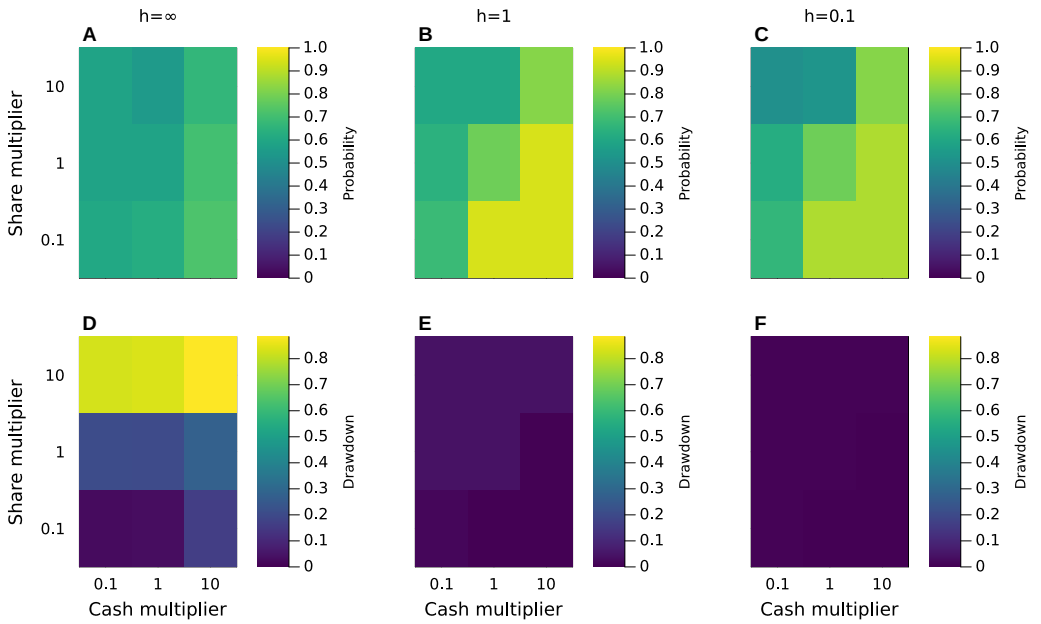

Figure 6: Crossed trader cash and share interventions at activation for the endogenous boundary, $f = 0.18$, and 50 seeds. Columns correspond to dealer capacities $h = \infty$, 1, and 0.1; cash multipliers run horizontally and share multipliers vertically. **(A–C)** Transition probability. **(D–F)** Median maximum drawdown on one common color scale. The matched held-boundary lattice was invariant across all nine interventions.

A Supplementary methods and validation

A.1 One complete simulation step

Every campaign used the complete update in Algorithm S1, with order clearing and settlement defined in Algorithm S2. Orders at step t came from the lattice X_{t-1} and the boundary states $e_{i,t-1}$, settled at the standing quote P_{t-1}, and generated the new quote P_t. The new quote classified the boundary before the cellular automaton (CA) produced X_t. Stating the full order of operations was necessary because changing that order would define a different model.

Algorithm S1 One endogenous-market step, $t-1 \to t$, in simulation order. Orders came from the old interior and boundary states, settled at the old quote, and generated the new quote. The new quote set the boundary before the interior cellular automaton update.

Require: lattice X_{t-1}; boundary states $e_i(t-1)$; trader books; dealer ledger; quote and band state $(P_{t-1}, \mu_{t-1}, \sigma_{t-1})$; rule field R_i; parameters; simulation seed
Ensure: lattice X_t; boundary states $e_i(t)$; settled books and dealer; quote and band state (P_t, μ_t, σ_t); all order counts

if t is the scheduled rule-quench step **then**
  $R_i \leftarrow 19286$ for every preselected target site i {preserve every dynamic state variable}
end if
if t is a scheduled balance-sheet intervention **then**
  for all traders i **do**
    $w_i \leftarrow g_w w_i$; $q_i \leftarrow \mathrm{round}(g_q q_i)$
  end for
end if
call Algorithm S2 using states at $t-1$ and P_{t-1}
receive $(n_t^B, n_t^S, u_t^B, u_t^S, r_t^B, r_t^S)$ and settled ledgers
$\phi_t \leftarrow (n_t^B - n_t^S)/N_{\mathrm{tr}}$
$P_t \leftarrow P_{t-1}\exp(\lambda\phi_t)$
$\mu_t \leftarrow \mu_{t-1} + \alpha(P_t - \mu_{t-1})$
$\sigma_t \leftarrow \sigma_{t-1} + \alpha(|P_t - \mu_t| - \sigma_{t-1})$
if boundary mode is endogenous **then**
  for all active boundary traders i **do**
    $e_i(t) \leftarrow 0$ if $P_t < \mu_t - k_i\sigma_t$; 2 if $P_t > \mu_t + k_i\sigma_t$; 1 otherwise
  end for
else
  $e_i(t) \leftarrow 1$ for every active boundary trader i
end if
write $e_i(t)$ to active boundary sites; leave passive sites at Hold
for all strictly interior sites i, simultaneously **do**
  $c_i(t) \leftarrow \sum_{j\in\partial i} s_j$ using old interior states and new boundary states
  $s_i(t) \leftarrow \mathcal{R}_{R_i}(c_i(t))$
end for

Algorithm S2 Order eligibility, dealer clearing, rationing, and settlement at P_{t-1}. The finite dealer filled only the unmatched residual. The $h = \infty$ branch filled every eligible order.

Require: old interior and boundary states; books $(w_i, q_i, \bar{c}_i)$; dealer (W_{t-1}, Q_{t-1}) and bounds $(Q_{\min}, Q_{\max}, C)$; P_{t-1}; h; cost-basis toggle; seed and step t

Ensure: settled books and dealer; executed counts (n_t^B, n_t^S); agent suppression (u_t^B, u_t^S); dealer rejection (r_t^B, r_t^S)

$\mathcal{B}, \mathcal{S} \leftarrow \varnothing$; $u_t^B, u_t^S \leftarrow 0$
for all interior traders, followed by active-boundary traders i **do**
  $o_i \leftarrow +1$ for Buy, -1 for Sell, and 0 for Hold {an edge trader reads its stored boundary state}
  if $o_i = +1$ and $w_i \geq P_{t-1}$ **then**
    append i to $\mathcal{B}$
  else if $o_i = -1$, $q_i \geq 1$, and the cost-basis test passes **then**
    append i to $\mathcal{S}$
  else if $o_i = +1$ **then**
    $u_t^B \leftarrow u_t^B + 1$
  else if $o_i = -1$ **then**
    $u_t^S \leftarrow u_t^S + 1$
  end if
end for
$B_t \leftarrow |\mathcal{B}|$; $S_t \leftarrow |\mathcal{S}|$; $n_t^B \leftarrow B_t$; $n_t^S \leftarrow S_t$
if $h < \infty$ and $B_t > S_t$ **then**
  $K_t^B \leftarrow Q_{t-1} - Q_{\min}$ {shares that the dealer could sell}
  $n_t^B \leftarrow S_t + \min(B_t - S_t, K_t^B)$
else if $h < \infty$ and $S_t > B_t$ **then**
  $K_t^S \leftarrow \min(Q_{\max} - Q_{t-1}, \lfloor (W_{t-1} + C)/P_{t-1} \rfloor)$ {$C = 0$ for every finite dealer in this study}
  $n_t^S \leftarrow B_t + \min(S_t - B_t, K_t^S)$
end if
$r_t^B \leftarrow B_t - n_t^B$; $r_t^S \leftarrow S_t - n_t^S$
if $r_t^B > 0$ **then**
  sort $\mathcal{B}$ by $z(\text{seed}, t, i, +1)$, then by trader identity
end if
if $r_t^S > 0$ **then**
  sort $\mathcal{S}$ by $z(\text{seed}, t, i, -1)$, then by trader identity
end if
for all the first n_t^B traders i in $\mathcal{B}$ **do**
  $\bar{c}_i \leftarrow (\bar{c}_i q_i + P_{t-1})/(q_i + 1)$; $q_i \leftarrow q_i + 1$; $w_i \leftarrow w_i - P_{t-1}$
end for
for all the first n_t^S traders i in $\mathcal{S}$ **do**
  $q_i \leftarrow q_i - 1$; $w_i \leftarrow w_i + P_{t-1}$ {$\bar{c}_i$ was unchanged on a sale}
end for
$W_t \leftarrow W_{t-1} + P_{t-1}(n_t^B - n_t^S)$
$Q_t \leftarrow Q_{t-1} + n_t^S - n_t^B$
return $(n_t^B, n_t^S, u_t^B, u_t^S, r_t^B, r_t^S)$ and settled ledgers

The algorithm kept two forms of nonexecution separate. Agent suppression meant that the trader lacked cash or shares before matching. Dealer rejection meant that the trader was eligible but the finite dealer could not absorb the unmatched residual. Neither event altered the trader's CA state. This distinction prevented a financial constraint from silently rewriting the behavioral state that generated the order.

A.2 Rationing and paired reproducibility

When dealer capacity bound, only the excess side required rationing. Each eligible trader on that side received a 64-bit score from a SplitMix64 finalizer applied to the tuple $(\text{seed}, t, \text{trader identity}, \text{side})$. We sorted orders by score and used trader identity as a deterministic tie breaker. Priorities changed with t, so a trader who submitted the same order repeatedly did not retain the same position. Paired

arms also used the same score for a given (t, i, side) after their eligible sets diverged. The score did not consume draws from the random-number generator used to construct the lattice and quenched disorder. The resulting rationing was reproducible without giving the same traders permanent priority.

For every rule-quench pair, we asserted exact equality of the frame at T_{pre}, the Sell-fraction history through that frame, the edge coordinates and band widths, and the price history through the quote formed from the common pre-quench state. For every held-boundary balance-sheet cell we also asserted equality of the complete Sell-fraction history and final frame across all nine cash–share interventions. The assertions tested that paired experiments differed only at the stated intervention.

A.3 Conservation and limiting cases

With no intervention, agent-plus-dealer cash and shares are invariants:

$$\sum_i w_i(t) + W_t = \sum_i w_i(0) + W_0, \tag{10}$$

$$\sum_i q_i(t) + Q_t = \sum_i q_i(0) + Q_0. \tag{11}$$

Across the production reservoir and finite-size campaigns, the maximum absolute cash error was 2.53×10^{-6} and the share error was zero. In the balance-sheet campaign, conservation was checked separately before and after the intentional intervention jump; its maximum cash error was 9.47×10^{-7} and its share error was zero.

Three exact limits supplied regression tests. With $h = \infty$, every agent-eligible order filled, and the complete path reproduced the earlier fill-all implementation. With $h = 0$, only opposing agent orders cleared, executed imbalance was zero, the price stayed fixed, and the endogenous-boundary lattice matched the held-boundary lattice. In the reservoir campaign, $h = 10$ never rejected an order and reproduced the $h = \infty$ paths exactly. The $h = 10$ equality held for the stated endowments and horizon; it was not a general identity between finite and unlimited dealers.

A.4 Campaign inventory

The production inventory contained 30,550 simulations across the four campaigns (Table S1). The reservoir campaign reused one dormant control within each $(h, \text{boundary}, \text{seed})$ cell, so its comma-separated value file contained one treated summary row per target fraction without duplicating the control. The other campaigns reconstructed a deterministic row order from independently checkpointed cells after threaded computation. This organization made a resumed threaded run reproduce the same tables as an uninterrupted run.

Table S1: Production campaign design. "Endogenous/held" indicates that both matched boundary conditions were run.

Campaign	Lattice sizes	Dealer h	Boundary	Seeds	Simulations
Selected paired quench	64	∞	endogenous	50	400
Reservoir screen	64	0–$10, \infty$	endogenous/held	50	9,600
Finite-size quench	32–128	$1, \infty$	three distinct arms	50	9,750
Cash–share factorial	64	$0.1, 1, \infty$	endogenous/held	50	10,800

The repository retained the earlier external-price classroom implementation and its archived Invesco QQQ exchange-traded fund input for provenance. No result from that model entered the principal analysis or figures.
